

UNIT III (GE8151 PROBLEM SOLVING AND PYTHON PROGRAMMING)

3.1. Boolean values and operators

BOOLEAN VALUES:

Boolean values can be tested for truth value, and used for IF and WHILE condition. There are two values True and False. 0 is considered as False and all other values considered as True.

Boolean Operations:

Consider x=True, y= False

Operator	Example	Description
and	x and y- returns false	Both operand should be true
or	x or y- returns true	Anyone of the operand should be true
not	not x returns false	Not carries single operand

Modulus operator

The **modulus operator** works on integers and yields the remainder when the first operand is divided by the second. In Python, the modulus operator is a percent sign (%). The syntax is the same as for other operators:

```
>>> quotient = 7 / 3
```

```
>>> print quotient
```

```
2
```

```
>>> remainder = 7 % 3
```

```
>>> print remainder
```

```
1
```

So 7 divided by 3 is 2 with 1 left over.

The modulus operator turns out to be surprisingly useful. For example, you can check whether one number is divisible by another—if $x \% y$ is zero, then x is divisible by y .

Also, you can extract the right-most digit or digits from a number. For example, $x \% 10$ yields the right-most digit of x (in base 10). Similarly $x \% 100$ yields the last two digits.

Boolean expressions

A **boolean expression** is an expression that is either true or false. The following examples use the operator `==`, which compares two operands and produces `True` if they are equal and `False` otherwise:

```
>>> 5 == 5
```

```
True
```

```
>>> 5 == 6
```

```
False
```

`True` and `False` are special values that belong to the type `bool`; they are not strings:

```
>>> type(True)
```

```
<type 'bool'>
```

```
>>> type(False)
```

```
<type 'bool'>
```

The `==` operator is one of the **relational operators**; the others are:

`x != y` # x is not equal to y

`x > y` # x is greater than y

`x < y` # x is less than y

`x >= y` # x is greater than or equal to y

`x <= y` # x is less than or equal to y

Logical operators

There are three **logical operators**: and, or, and not. The semantics (meaning) of these operators is similar to their meaning in English. For example, $x > 0$ and $x < 10$ is true only if x is greater than 0 and less than 10. $n\%2 == 0$ or $n\%3 == 0$ is true if either of the conditions is true, that is, if the number is divisible by 2 or 3.

Finally, the not operator negates a boolean expression, so $\text{not } (x > y)$ is true if $x > y$ is false, that is, if x is less than or equal to y . The operands of the logical operators should be boolean expressions. Any nonzero number is interpreted as "true."

```
>>> 17 and True
```

```
True
```
